1 Introduction

This document describes StackwalkerAPI, an API and library for walking a call stack. The call stack (also known as the run-time stack) is a stack found in a process that contains the currently active stack frames. Each stack frame is a record of an executing function (or function-like object such as a signal handler or system call). StackwalkerAPI provides an API that allows users to collect a call stack (known as walking the call stack) and access information about its stack frames. The current implementation supports Linux/x86, Linux/x86-64, Linux/Power, Linux/Power-64, Windows/x86, BlueGene/L, and BlueGene/P.

StackwalkerAPI is designed to be both easy-to-use and easy-to-extend. Users can easily use StackwalkerAPI to walk a call stack without needing to understand how call stacks are laid out on their platform. Users can easily extend StackwalkerAPI to work with new platforms and types of stack frames by implementing a set of callbacks that can be plugged into StackwalkerAPI.

StackwalkerAPI's ease-of-use comes from it providing a platform independent interface that allows users to access detailed information about the call stack. For example, the following C++ code-snippet is all that is needed to walk and print the call stack of the currently running thread.

StackwalkerAPI can walk a call stack in the same address space as where the StackwalkerAPI library lives (known as a first party stackwalk), or it can walk a call stack in another process (known as a third party stackwalk). To change the above example to perform a third party stackwalk, we would only need to pass a process identifier to newWalker, e.g:

```
Walker *walker = Walker::newWalker(pid);
```

Our other design goal with StackwalkerAPI is to make it easy-to-extend. The mechanics of how to walk through a stack frame can vary between different platforms, and even between different types of stack frames on the same platform. In addition, different platforms may have different mechanisms for reading the data in a call stack or looking up symbolic names that go with a stack frame. StackwalkerAPI provides a callback interface for plugging in mechanisms for handling new systems and types of stack frames. The callback interface can be used to port StackwalkerAPI to new platforms, extend StackwalkerAPI support on existing systems, or more easily integrate StackwalkerAPI into existing tools. There are callbacks for the following StackwalkerAPI operations:

Walk through a stack frame StackwalkerAPI will find different types of stack frames on different platforms and even within the same platform. For example, on Linux/x86 the stack frame generated by a typical function looks different from the stack frame generated by a signal

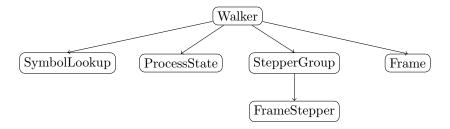

Figure 1: Object Ownership

handler. The callback interface can be used to register a handler with StackwalkerAPI that knows how to walk through a new type of stack frame. For example, the DyninstAPI tool registers an object with StackwalkerAPI that describes how to walk through the stack frames generated by its instrumentation.

Access process data To walk a call stack, StackwalkerAPI needs to be able to read a process' memory and registers. When doing a first party stackwalk, this is done by directly reading them from the current address space. When doing a third party stackwalk, this is done by reading them using a debugger interface. The callback interface can be used to register new objects for accessing process data. This can be used, for example, to port StackwalkerAPI to a new operating system or make it work with a new debugger interface.

Look up symbolic names When StackwalkerAPI finds a stack frame, it gets an address that points into the piece of code that created that stack frame. This address is not necessarily meaningful to a user, so StackwalkerAPI attempts to associate the address with a symbolic name. The callback interface can be used to register an object with StackwalkerAPI that performs an address to name mapping, allowing StackwalkerAPI to associate names with stack frames.

2 Abstractions

StackwalkerAPI contains two interfaces: the Stackwalking Interface and the Callback Interface. The stackwalking interface is used to walk the call stack, query information about stack frames, and collect basic information about threads. The Callback Interface is used to provide custom mechanisms for walking a call stack. Users who operate in one of StackwalkerAPI's standard configurations do not need to use the Callback Interface.

Figure 1 shows the ownership hierarchy for StackwalkerAPI's classes. Ownership is a "contains" relationship; if one class owns another, then instances of the owner class maintain an exclusive instance of the other. For example, in Figure 1 the each Walker instance contains exactly one instance of a ProcessState object. No other instance of Walker uses that instance of ProcessState.

This remainder of this section briefly describes the six classes that make up StackwalkerAPI's two interfaces. For more details, see the class descriptions in Section 3.

2.1 Stackwalking Interface

Walker The Walker class is the top-level class used for collecting stackwalks. It provides a simple interface for requesting a stackwalk. Each Walker object is associated with one process, but may walk the call stacks of multiple threads within that process.

Frame A call stack is returned as a vector of Frame objects, where each Frame object represents a stack frame. It can provide information about the stack frame and basic information about the function, signal handler or other mechanism that created it. Users can request information such as the symbolic name associated with the Frame object, and values of its saved registers.

2.2 Callback Interface

StackwalkerAPI includes default implementations of the Callback Interface on each of its supported platforms. These default implementations allow StackwalkerAPI to work "out of the box" in a standard configuration on each platform. Users can port StackwalkerAPI to new platforms or customize its call stack walking behavior by implementing their own versions of the classes in the Callback Interface.

FrameStepper A FrameStepper object describes how to walk through a single type of stack frame. Users can provide an implementation of this interface that allows StackwalkerAPI to walk through new types of stack frames. For example, the DyninstAPI uses this interface to extend StackwalkerAPI to allow it to walk through stack frames created by instrumentation code.

StepperGroup A StepperGroup is a collection of FrameStepper objects and criteria that describes when to use each type of FrameStepper. These criteria are based on simple address ranges in the code space of the target process. In the above example with DyninstAPI, it would be the job of the StepperGroup to identify a stack frame as belonging to instrumentation code and use the instrumentation FrameStepper to walk through it.

ProcessState A ProcessState interface describes how to access data in the target process. To walk a call stack, StackwalkerAPI needs to access both registers and memory in the target process; ProcessState provides an interface that StackwalkerAPI can use to access that information. StackwalkerAPI includes two default implementation of ProcessState for each platform: one to collect a first party stackwalk in the current process, and one that uses a debugger interface to collect a third party stackwalk in another process.

SymbolLookup The SymbolLookup interface is used to associate a symbolic name with a stack frame. A stackwalk returns a collection of addresses in the code space of a binary. This class uses the binary's symbol table to map those addresses into symbolic names. A default implementation of this class, which uses the DynSymtab package, is provided with StackwalkerAPI. A user could, for example, use this interface to allow StackwalkerAPI to use libelf to look up symbol names instead.

3 API Reference

This section describes the StackwalkerAPI interface. It is divided into three sub-sections: a description of the definitions and basic types used by this API, a description of the interface for collecting stackwalks, and a description of the callback interface.

3.1 Definitions and Basic Types

The following definitions and basic types are referenced throughout the rest of this manual.

3.1.1 Definitions

- Stack Frame A stack frame is a record of a function (or function-like object) invocation. When a function is executed, it may create a frame on the call stack. StackwalkerAPI finds stack frames and returns a description of them when it walks a call stack. The following three definitions deal with stack frames.
- Bottom of the Stack The bottom of the stack is the earliest stack frame in a call stack, usually a thread's initial function. The stack grows from bottom to the top.
- **Top of the Stack** The top of the stack is the most recent stack frame in a call stack. The stack frame at the top of the stack is for the currently executing function.
- **Frame Object** A Frame object is StackwalkerAPI's representation of a stack frame. A Frame object is a snapshot of a stack frame at a specific point in time. Even if a stack frame changes as a process executes, a Frame object will remain the same. Each Frame object is represented by an instance of the Frame class.

The following three definitions deal with fields in a Frame object.

- SP (Stack Pointer) A Frame object's SP member points to the top of its stack frame (a stack frame grows from bottom to top, similar to a call stack). The Frame object for the top of the stack has a SP that is equal to the value in the stack pointer register at the time the Frame object was created. The Frame object for any other stack frame has a SP that is equal to the top address in the stack frame.
- **FP** (Frame Pointer) A Frame object's FP member points to the beginning (or bottom) of its stack frame. The Frame object for the top of the stack has a FP that is equal to the value in the frame pointer register at the time the Frame object was created. The Frame object for any other stack frame has a FP that is equal to the beginning of the stack frame.
- **RA** (Return Address) A Frame object's RA member points to the location in the code space where control will resume when the function that created the stack frame resumes. The Frame object for the top of the stack has a RA that is equal to the value in the program counter register at the time the Frame object was created. The Frame object for any other stack frame has a RA that is found when walking a call stack.

```

Figure 3: Stack Frame and Frame Object Layout (ARMv8 Architecture)

Figure 2 shows the relationship between application code, stack frames, and Frame objects. In the figure, the source code on the left has run through the main and foo functions, and into the bar function. It has created the call stack in the center, which is shown as a sequence of words growing down. The current values of the processor registers, while executing in bar, are shown below the call stack. When StackwalkerAPI walks the call stack, it creates the Frame objects shown on the right. Each Frame object corresponds to one of the stack frames found in the call stack or application registers.

The call stack in Figure 2 is similar to one that would be found on the x86 architecture. Details about how the call stack is laid out may be different on other architectures, but the meanings of the FP, SP, and RA fields in the Frame objects will remain the same. The layout of the ARM64 stack may be found in Figure 3 as an example of the scope of architectural variations.

The following four definitions deal with processes involved in StackwalkerAPI.

Target Process The process from which StackwalkerAPI is collecting stackwalks.

Host Process The process in which StackwalkerAPI code is currently running.

First Party Stackwalk StackwalkerAPI collects first party stackwalk when it walks a call stack in the same address space it is running in, i.e. the target process is the same as the host process.

Third Party Stackwalk StackwalkerAPI collects third party stackwalk when it walks the call stack in a different address space from the one it is running in, i.e. the target process is different from the host process. A third party stackwalk is usually done through a debugger interface.

3.1.2 Basic Types

typedef unsigned long Address

An integer value capable of holding an address in the target process. Address variables should not, and in many cases cannot, be used directly as a pointer. It may refer to an address in a different process, and it may not directly match the target process' pointer representation. Address is guaranteed to be at least large enough to hold an address in a target process, but may be larger.

typedef ... Dyninst::PID

A handle for identifying a process. On UNIX systems this will be an integer representing a PID. On Windows this will be a HANDLE object.

typedef ... Dyninst::THR_ID

A handle for identifying a thread. On Linux and BlueGene platforms this is an integer referring to a TID (Thread Identifier). On Windows it is a HANDLE object.

class Dyninst::MachRegister

A value that names a machine register.

typedef unsigned long Dyninst::MachRegisterVal

A value that holds the contents of a register. A Dyninst::MachRegister names a specific register, while a Dyninst::MachRegisterVal represents the value that may be in that register.

3.2 Namespace StackwalkerAPI

The classes in Section 3.3 and Section 3.5 fall under the C++ namespace Dyninst::Stackwalker. To access them, a user should refer to them using the Dyninst::Stackwalker:: prefix, e.g. Dyninst::Stackwalker::Walker. Alternatively, a user can add the C++ using keyword above any references to StackwalkerAPI objects, e.g., using namespace Dyninst and using namespace Stackwalker.

3.3 Stackwalking Interface

This section describes StackwalkerAPI's interface for walking a call stack. This interface is sufficient for walking call stacks on all the systems and variations covered by our default callbacks.

To collect a stackwalk, first create new Walker object associated with the target process via

Walker::newWalker()

or

Walker::newWalker(Dyninst::PID pid)

Once a Walker object has been created, a call stack can be walked with the

Walker::walkStack

method. The new stack walk is returned as a vector of Frame objects.

3.3.1 Class Walker

Defined in: walker.h

The Walker class allows users to walk call stacks and query basic information about threads in a target process. The user should create a Walker object for each process from which they are walking call stacks. Each Walker object is associated with one process, but may walk call stacks on multiple threads within that process. The Walker class allows users to query for the threads available for walking, and it allows you to specify a particular thread whose call stack should be walked. Stackwalks are returned as a vector of Frame objects.

Each Walker object contains three objects:

- ProcessState
- StepperGroup
- SymbolLookup

These objects are part of the Callback Interface and can be used to customize StackwalkerAPI. The ProcessState object tells Walker how to access data in the target process, and it determines whether this Walker collects first party or third party stackwalks. Walker will pick an appropriate default ProcessState object based on which factory method the users calls. The StepperGroup object is used to customize how the Walker steps through stack frames. The SymbolLookup object is used to customize how StackwalkerAPI looks up symbolic names of the function or object that created a stack frame.

These factory methods return new Walker objects:

- The first takes no arguments and returns a first-party stackwalker.
- The second takes a PID representing a running process and returns a third-party stackwalker on that process.
- The third takes the name of the executing binary in addition to the PID and also returns a third-party stackwalker on that process.
- The fourth takes a ProcControlAPI process object and returns a third-party stackwalker.
- The fifth takes the name of an executable and its arguments, creates the process, and returns a third-party stackwalker.
- The sixth takes a ProcessState pointer representing a running process as well as user-defined Stepper-Group and SymbolLookup pointers. It can return both first-party and third-party Walkers, depending on the ProcessState parameter.

Unless overriden with the sixth variant, the new Walker object uses the default StepperGroup and SymbolLookup callbacks for the current platform. First-party walkers use the ProcSelf callback for its ProcessState object. Third-party walkers use ProcDebug instead. See Section 3.5.1 for more information about defaults in the Callback Interface.

This method returns NULL if it was unable to create a new Walker object. The new Walker object was created with the new operator, and should be deallocated with the delete operator when it is no longer needed.

This method attaches to a group of processes and returns a vector of Walker objects that perform third-party stackwalks. As above, the first variant takes a list of PIDs and attaches to those processes; the second variant also specifies the executable binary.

This method walks a call stack in the process associated with this Walker. The call stack is returned as a vector of Frame objects in stackwalk. The top of the stack is returned in index 0 of stackwalk, and the bottom of the stack is returned in index stackwalk.size()-1.

A stackwalk can be taken on a specific thread by passing a value in the thread parameter. If thread has the value NULL_THR_ID, then a default thread will be chosen. When doing a third party stackwalk, the default thread will be the process' initial thread. When doing a first party stackwalk, the default thread will be the thread that called walkStack. The default StepperGroup provided to a Walker will support collecting call stacks from almost all types of functions, including signal handlers and optimized, frameless functions.

This method returns true on success and false on failure.

```
bool walkStackFromFrame(std::vector<Frame> &stackwalk, const Frame &frame)
```

This method walks a call stack starting from the given stack frame, frame. The call stack will be output in the stackwalk vector, with frame stored in index 0 of stackwalk and the bottom of the stack stored in index stackwalk.size()-1.

This method returns true on success and false on failure.

```
bool walkSingleFrame(const Frame &in, Frame &out)
```

This methods walks through single frame, in. Parameter out will be set to in's caller frame.

This method returns true on success and false on failure.

```
bool getInitialFrame(Frame &frame, Dyninst::THR_ID thread = NULL_THR_ID)
```

This method returns the Frame object on the top of the stack in parameter frame. Under walkStack, frame would be the one returned in index 0 of the stackwalk vector. A stack frame can be found on a specific thread by passing a value in the thread parameter. If thread has the value NULL_THR_ID, then a default thread will be chosen. When doing a third party stackwalk, the default thread will be the process' initial thread. When doing a first party stackwalk, the default thread will be the thread that called getInitialFrame.

This method returns true on success and false on failure.

bool getAvailableThreads(std::vector<Dyninst::THR_ID> &threads)

This method returns a vector of threads in the target process upon which StackwalkerAPI can walk call stacks. The threads are returned in output parameter threads. Note that this method may return a subset of the actual threads in the process. For example, when walking call stacks on the current process, it is only legal to walk the call stack on the currently running thread. In this case, getAvailableThreads returns a vector containing only the current thread.

This method returns true on success and false on failure.

ProcessState *getProcessState() const

This method returns the ProcessState object associated with this Walker.

StepperGroup *getStepperGroup() const

This method returns the StepperGroup object associated with this Walker.

SymbolLookup *getSymbolLookup() const

This method returns the SymbolLookup object associated with this Walker.

bool addStepper(FrameStepper *stepper)

This method adds a provided FrameStepper to those used by the Walker.

static SymbolReaderFactory *getSymbolReader()

This method returns a factory for creating process-specific symbol readers. Unlike the above methods it is global across all Walkers and is thus defined static.

static void setSymbolReader(SymbolReaderFactory *);

Set the symbol reader factory used when creating Walker objects.

```
static void version(int &major, int &minor, int &maintenance)
```

This method returns version information (e.g., 8, 0, 0 for the 8.0 release).

3.3.2 Class Frame

Defined in: frame.h

The Walker class returns a call stack as a vector of Frame objects. As described in Section 3.1.1, each Frame object represents a stack frame, and contains a return address (RA), stack pointer (SP) and frame pointer (FP). For each of these values, optionally, it stores the location where the values were found. Each Frame object may also be augmented with symbol information giving a function name (or a symbolic name, in the case of non-functions) for the object that created the stack frame.

The Frame class provides a set of functions (getRALocation, getSPLocation and getFPLocation) that return the location in the target process' memory or registers where the RA, SP, or FP were found. These functions may be used to modify the stack. For example, the DyninstAPI uses these functions to change return addresses on the stack when it relocates code. The RA, SP, and FP may be found in a register or in a memory address on a call stack.

This method creates a new Frame object and sets the mandatory data members: RA, SP and FP. The new Frame object is associated with walker.

The optional location fields can be set by the methods below.

The new Frame object is created with the new operator, and the user should be deallocate it with the delete operator when it is no longer needed.

```
bool operator==(const Frame &)
```

Frame objects have a defined equality operator.

```
Dyninst::MachRegisterVal getRA() const
```

This method returns this Frame object's return address.

```
void setRA(Dyninst::MachRegisterVal val)
```

This method sets this Frame object's return address to val.

```
Dyninst::MachRegisterVal getSP() const
```

This method returns this Frame object's stack pointer.

```
void setSP(Dyninst::MachRegisterVal val)
```

This method sets this Frame object's stack pointer to val.

```
Dyninst::MachRegisterVal getFP() const
```

This method returns this Frame object's frame pointer.

```
void setFP(Dyninst::MachRegisterVal val)
```

This method sets this Frame object's frame pointer to val.

```
bool isTopFrame() const;
bool isBottomFrame() const;
```

These methods return whether a Frame object is the top (e.g., most recently executing) or bottom of the stack walk.

```
typedef enum {
    loc_address,
    loc_register,
    loc_unknown
} storage_t;

typedef struct {
    union {
        Dyninst::Address addr;
        Dyninst::MachRegister reg;
    } val;
    storage_t location;
} location_t;
```

The location_t structure is used by the getRALocation, getSPLocation, and getFPLocation methods to describe where in the process a Frame object's RA, SP, or FP were found. When walking a call stack these values may be found in registers or memory. If they were found in

memory, the location field of location_t will contain loc_address and the addr field will contain the address where it was found. If they were found in a register the location field of location_t will contain loc_register and the reg field will refer to the register where it was found. If this Frame object was not created by a stackwalk (using the newframe factory method, for example), and has not had a set location method called, then location will contain loc_unknown.

location_t getRALocation() const

This method returns a location_t describing where the RA was found.

void setRALocation(location_t newval)

This method sets the location of where the RA was found to newval.

location_t getSPLocation() const

This method returns a location_t describing where the SP was found.

void setSPLocation(location_t newval)

This method sets the location of where the SP was found to newval.

location_t getFPLocation() const

This method returns a location_t describing where the FP was found.

void setFPLocation(location_t newval)

This method sets the location of where the FP was found to newval.

bool getName(std::string &str) const

This method returns a stack frame's symbolic name. Most stack frames are created by functions, or function-like objects such as signal handlers or system calls. This method returns the name of the object that created this stack frame. For stack frames created by functions, this symbolic name will be the function name. A symbolic name may not always be available for all Frame objects, such as in cases of stripped binaries or special stack frames types.

The function name is obtained by using this Frame object's RA to call the SymbolLookup callback. By default StackwalkerAPI will attempt to use the SymtabAPI package to look up symbol names in binaries. If SymtabAPI is not found, and no alternative SymbolLookup object is present, then this method will return an error.

This method returns true on success and false on error.

bool getObject(void* &obj) const

In addition to returning a symbolic name (see getName) the SymbolLookup interface allows for an opaque object, a void*, to be associated with a Frame object. The contents of this void* is determined by the SymbolLookup implementation. Under the default implementation that uses SymtabAPI, the void* points to a Symbol object or NULL if no symbol is found.

This method returns true on success and false on error.

Walker *getWalker() const;

This method returns the Walker object that constructed this stack frame.

THR_ID getThread() const;

This method returns the execution thread that the current Frame represents.

FrameStepper* getStepper() const

This method returns the FrameStepper object that was used to construct this Frame object in the stepper output parameter.

This method returns true on success and false on error.

```
bool getLibOffset(std::string &lib, Dyninst::Offset &offset, void* &symtab) const
```

This method returns the DSO (a library or executable) and an offset into that DSO that points to the location within that DSO where this frame was created. lib is the path to the library that was loaded, and offset is the offset into that library. The return value of the symtab parameter is dependent on the SymbolLookup implementation-by default it will contain a pointer to a Dyninst::Symtab object for this DSO. See the SymtabAPI Programmer's Guide for more information on using Dyninst::Symtab objects.

bool nonCall() const

This method returns whether a Frame object represents a function call; if false, the Frame may represent instrumentation, a signal handler, or something else.

3.4 Accessing Local Variables

Defined in: local_var.h

StackwalkerAPI can be used to access local variables found in the frames of a call stack. The StackwalkerAPI interface for accessing the values of local variables is closely tied to the SymtabAPI interface for collecting information about local variables—SymtabAPI handles for functions, local variables, and types are part of this interface.

Given an initial handle to a SymtabAPI Function object, SymtabAPI can look up local variables contained in that function and the types of those local variables. See the SymtabAPI Programmer's Guide for more information.

```
static Dyninst::SymtabAPI::Function *getFunctionForFrame(Frame f)
```

This method returns a SymtabAPI function handle for the function that created the call stack frame, f.

Given a local variable and a stack frame from a call stack, this function returns the value of the variable in that frame. The local variable is specified by the SymtabAPI variable object, var. swalk is a call stack that was collected via StackwalkerAPI, and frame specifies an index into that call stack that contains the local variable. The value of the variable is stored in out_buffer and the size of out_buffer should be specified in out_buffer_size.

A local variable only has a limited scope with-in a target process' execution. StackwalkerAPI cannot guarantee that it can collect the correct return value of a local variable from a call stack if the target process is continued after the call stack is collected.

Finding and collecting the values of local variables is dependent on debugging information being present in a target process' binary. Not all binaries contain debugging information, and in some cases, such as for binaries built with high compiler optimization levels, that debugging information may be incorrect.

getLocalVariableValue will return on of the following values:

glvv Success getLocalVariableValue was able to correctly read the value of the given variable.

- glvv_EParam An error occurred, an incorrect parameter was specified (frame was larger than swalk.size(), or var was not a variable in the function specified by frame).
- glvv_EOutOfScope An error occurred, the specified variable exists in the function but isn't live at the current execution point.
- glvv EBufferSize An error occurred, the variable's value does not fit inside out_buffer.
- glvv_EUnknown An unknown error occurred. It is most likely that the local variable was optimized away or debugging information about the variable was incorrect.

3.5 Callback Interface

This subsection describes the Callback Interface for StackwalkerAPI. The Callback Interface is primarily used to port StackwalkerAPI to new platforms, extend support for new types of stack frames, or integrate StackwalkerAPI into existing tools.

The classes in this subsection are interfaces, they cannot be instantiated. To create a new implementation of one of these interfaces, create a new class that inherits from the callback class and implement the necessary methods. To use a new ProcessState, StepperGroup, or SymbolLookup class with StackwalkerAPI, create a new instance of the class and register it with a new Walker object using the

```
Walker::newWalker(ProcessState *, StepperGroup *, SymbolLookup *)
```

factory method (see Section 3.3.1). To use a new FrameStepper class with StackwalkerAPI, create a new instance of the class and register it with a StepperGroup using the

```
StepperGroup::addStepper(FrameStepper *)
```

method (see Section 3.5.3).

Some of the classes in the Callback Interface have methods with default implementations. A new class that inherits from a Callback Interface can optionally implement these methods, but it is not required. If a method requires implementation, it is written as a C++ pure virtual method (virtual funcName() = 0). A method with a default implementation is written as a C++ virtual method (virtual funcName()).

3.5.1 Default Implementations

The classes described in the Callback Interface are C++ abstract classes, or interfaces. They cannot be instantiated. For each of these classes StackwalkerAPI provides one or more default implementations on each platform. These default implementations are classes that inherit from the abstract classes described in the Callback Interface. If a user creates a Walker object without providing their own FrameStepper, ProcessState, and SymbolLookup objects, then StackwalkerAPI will use the default implementations listed in Table 1. These implementations are described in Section 4.2.

3.5.2 Class FrameStepper

Defined in: framestepper.h

	StepperGroup	ProcessState	SymbolLookup	FrameStepper
Linux/x86	1. AddrRange	1. ProcSelf	1. SwkSymtab	1. FrameFuncStepper
Linux/x86-64		2. ProcDebug		2. SigHandlerStepper
				3. DebugStepper
				4. AnalysisStepper
				5. StepperWanderer
				6. BottomOfStackStepper
Linux/PPC	1. AddrRange	1. ProcSelf	1. SwkSymtab	1. FrameFuncStepper
Linux/PPC-64		2. ProcDebug		2. SigHandlerStepper
				3. AnalysisStepper
Windows/x86	1. AddrRange	1. ProcSelf	1. SwkSymtab	1. FrameFuncStepper
		2. ProcDebug		2. AnalysisStepper
				3. StepperWanderer
				4. BottomOfStackStepper
BlueGene	1. AddrRange	1. ProcDebug	1. SwkSymtab	1. FrameFuncStepper

Table 1: Callback Interface Defaults

The FrameStepper class is an interface that tells StackwalkerAPI how to walk through a specific type of stack frame. There may be many different ways of walking through a stack frame on a platform, e.g, on Linux/x86 there are different mechanisms for walking through system calls, signal handlers, regular functions, and frameless functions. A single FrameStepper describes how to walk through one of these types of stack frames.

A user can create their own FrameStepper classes that tell StackwalkerAPI how to walk through new types of stack frames. A new FrameStepper object must be added to a StepperGroup before it can be used.

In addition to walking through individual stack frames, a FrameStepper tells its StepperGroup when it can be used. The FrameStepper registers address ranges that cover objects in the target process' code space (such as functions). These address ranges should contain the objects that will create stack frames through which the FrameStepper can walk. If multiple FrameStepper objects have overlapping address ranges, then a priority value is used to determine which FrameStepper should be attempted first.

FrameStepper is an interface class; it cannot be instantiated. Users who want to develop new FrameStepper objects should inherit from this class and implement the desired virtual functions. The getCallerFrame, getPriority, and getName functions must be implemented; all others may be overridden if desired.

```
typedef enum {
    gcf_success,
    gcf_stackbottom,
    gcf_not_me,
    gcf_error
} gcframe_ret_t

virtual gcframe_ret_t getCallerFrame(const Frame &in, Frame &out) = 0
```

This method walks through a single stack frame and generates a Frame object that represents the caller's stack frame. Parameter in will be a Frame object that this FrameStepper is capable of

walking through. Parameter out is an output parameter that this method should set to the Frame object that called in.

There may be multiple ways of walking through a different types of stack frames. Each FrameStepper class should be able to walk through a type of stack frame. For example, on x86 one FrameStepper could be used to walk through stack frames generated by ABI-compliant functions; out's FP and RA are found by reading from in's FP, and out's SP is set to the word below in's FP. A different FrameStepper might be used to walk through stack frames created by functions that have optimized away their FP. In this case, in may have a FP that does not point out's FP and RA. The FrameStepper will need to use other mechanisms to discover out's FP or RA; perhaps the FrameStepper searches through the stack for the RA or performs analysis on the function that created the stack frame.

If getCallerFrame successfully walks through in, it is required to set the following parameters in out. See Section 3.3.2 for more details on the values that can be set in a Frame object:

Return Address (RA) The RA should be set with the Frame::setRA method.

Stack Pointer (SP) The SP should be set with the Frame::setSP method.

Frame Pointer (FP) The FP should be set with the Frame::setFP method

Optionally, getCallerFrame can also set any of following parameters in out:

Return Address Location (RALocation) The RALocation should be set with the Frame::setRALocation() method.

Stack Pointer Location (SPLocation) The SPLocation should be set with the Frame::setRALocation() method.

Frame Pointer Location (FPLocation) The FPLocation should be set with the Frame::setFPLocation() method.

If a location field in out is not set, then the appropriate Frame::getRALocation, Frame::getSPLocation or Frame::getFPLocation method will return loc_unknown.

getCallerFrame should return gcf_success if it successfully walks through in and creates an out Frame object. It should return gcf_stackbottom if in is the bottom of the stack and there are no stack frames below it. It should return gcf_not_me if in is not the correct type of stack frame for this FrameStepper to walk through. StackwalkerAPI will then attempt to locate another FrameStepper to handle in or abort the stackwalk. It should return gcf_error if there was an error and the stack walk should be aborted.

virtual void registerStepperGroup(StepperGroup *steppergroup)

This method is used to notify a FrameStepper when StackwalkerAPI adds it to a StepperGroup. The StepperGroup to which this FrameStepper is being added is passed in parameter steppergroup. This method can be used to initialize the FrameStepper (in addition to any FrameStepper constructor).

virtual unsigned getPriority() const = 0

This method is used by the StepperGroup to decide which FrameStepper to use if multiple FrameStepper objects are registered over the same address range (see addAddressRanges in Section 3.5.3 for more information about address ranges). This method returns an integer representing a priority level, the lower the number the higher the priority.

The default FrameStepper objects provided by StackwalkerAPI all return priorities between 0x1000 and 0x2000. If two FrameStepper objects have an overlapping address range, and they have the same priority, then the order in which they are used is undefined.

FrameStepper(Walker *w);

Constructor definition for all FrameStepper instances.

```
virtual ProcessState *getProcessState();
```

Return the ProcessState used by the FrameStepper. Can be overridden if the user desires.

```
virtual Walker *getWalker();
```

Return the Walker associated with the FrameStepper. Can be overridden if the user desires.

This function is called when a new library is loaded by the process; it should be implemented if the FrameStepper requires such information.

```
virtual const char *getName() const = 0;
```

Returns a name for the FrameStepper; must be implemented by the user.

3.5.3 Class StepperGroup

Defined in: steppergroup.h

The StepperGroup class contains a collection of FrameStepper objects. The StepperGroup's primary job is to decide which FrameStepper should be used to walk through a stack frame given a return address. The default StepperGroup keeps a set of address ranges for each FrameStepper. If multiple FrameStepper objects overlap an address, then the default StepperGroup will use a priority system to decide.

StepperGroup provides both an interface and a default implementation of that interface. Users who want to customize the StepperGroup should inherit from this class and re-implement any of the below virtual functions.

```
StepperGroup(Walker *walker)
```

This factory constructor creates a new StepperGroup object associated with walker.

```
virtual bool addStepper(FrameStepper *stepper)
```

This method adds a new FrameStepper to this StepperGroup. The newly added stepper will be tracked by this StepperGroup, and it will be considered for use when walking through stack frames.

This method returns true if it successfully added the FrameStepper, and false on error.

```
virtual bool addStepper(FrameStepper *stepper, Address start, Address
end) = 0;
```

Add the specified FrameStepper to the list of known steppers, and register it to handle frames in the range [start, end).

```
virtual void registerStepper(FrameStepper *stepper);
```

Add the specified FrameStepper to the list of known steppers and use it over the entire address space.

Given an address that points into a function (or function-like object), addr, this method decides which FrameStepper should be used to walk through the stack frame created by the function at that address. A pointer to the FrameStepper will be returned in parameter out.

It may be possible that the FrameStepper this method decides on is unable to walk through the stack frame (it returns gcf_not_me from FrameStepper::getCallerFrame). In this case StackwalkerAPI will call findStepperForAddr again with the last_tried parameter set to the failed FrameStepper. findStepperForAddr should then find another FrameStepper to use. Parameter last_tried will be set to NULL the first time getStepperToUse is called for a stack frame.

The default version of this method uses address ranges to decide which FrameStepper to use. The address ranges are contained within the process' code space, and map a piece of the code space to a FrameStepper that can walk through stack frames created in that code range. If multiple FrameStepper objects share the same range, then the one with the highest priority will be tried first.

This method returns true on success and false on failure.

```
typedef std::pair<std::string, Address> LibAddrPair;
typedef enum { library_load, library_unload } lib_change_t;
virtual void newLibraryNotification(LibAddrPair *libaddr, lib_change_t
change);
```

Called by the StackwalkerAPI when a new library is loaded.

```
Walker *getWalker() const
```

This method returns the Walker object that associated with this StepperGroup.

```
void getSteppers(std::set<FrameStepper *> &);
```

Fill in the provided set with all FrameSteppers registered in the StepperGroup.

3.5.4 Class ProcessState

Defined in: procstate.h

The ProcessState class is a virtual class that defines an interface through which StackwalkerAPI can access the target process. It allows access to registers and memory, and provides basic information about the threads in the target process. StackwalkerAPI provides two default types of ProcessState objects: ProcSelf does a first party stackwalk, and ProcDebug does a third party stackwalk.

A new ProcessState class can be created by inheriting from this class and implementing the necessary methods.

```
static ProcessState *getProcessStateByPid(Dyninst::PID pid)
```

Given a PID, return the corresponding ProcessState object.

```
virtual unsigned getAddressWidth() = 0;
```

Return the number of bytes in a pointer for the target process. This value is 4 for 32-bit platforms (x86, PowerPC-32) and 8 for 64-bit platforms (x86-64, PowerPC-64).

```
typedef enum { Arch_x86, Arch_x86_64, Arch_ppc32, Arch_ppc64 }
Architecture;
virtual Dyninst::Architecture getArchitecture() = 0;
```

Return the appropriate architecture for the target process.

This method takes a register name as input, reg, and returns the value in that register in val in the thread thread.

This method returns true on success and false on error.

```
virtual bool readMem(void *dest, Address source, size_t size) = 0
```

This method reads memory from the target process. Parameter dest should point to an allocated buffer of memory at least size bytes in the host process. Parameter source should contain an address in the target process to be read from. If this method succeeds, size bytes of memory is copied from source, stored in dest, and true is returned. This method returns false otherwise.

```
virtual bool getThreadIds(std::vector<Dyninst::THR_ID> &threads) = 0
```

This method returns a list of threads whose call stacks can be walked in the target process. Thread are returned in the threads vector. In some cases, such as with the default ProcDebug, this method returns all of the threads in the target process. In other cases, such as with ProcSelf, this method returns only the calling thread.

The first thread in the threads vector (index 0) will be used as the default thread if the user requests a stackwalk without specifying an thread (see Walker::WalkStack).

This method returns true on success and false on error.

```
virtual bool getDefaultThread(Dyninst::THR_ID &default_tid) = 0
```

This method returns the thread representing the initial process in the default_tid output parameter.

This method returns true on success and false on error.

```
virtual Dyninst::PID getProcessId()
```

This method returns a process ID for the target process. The default ProcessState implementations (ProcDebug and ProcSelf) will return a PID on UNIX systems and a HANDLE object on Windows.

```
Walker *getWalker() const;
```

Return the Walker associated with the current process state.

```
std::string getExecutablePath();
```

Returns the name of the executable associated with the current process state.

3.5.4.1 Class LibraryState Defined in: procstate.h

LibraryState is a helper class for ProcessState that provides information about the current DSOs (libraries and executables) that are loaded into a process' address space. FrameSteppers frequently use the LibraryState to get the DSO through which they are attempting to stack walk.

Each Library is represented using a LibAddrPair object, which is defined as follows:

typedef std::pair<std::string, Dyninst::Address> LibAddrPair

LibAddrPair.first refers to the file path of the library that was loaded, and LibAddrPair.second is the load address of that library in the process' address space. The load address of a library can be added to a symbol offset from the file in order to get the absolute address of a symbol.

virtual bool getLibraryAtAddr(Address addr, LibAddrPair &lib) = 0

This method returns a DSO, using the lib output parameter, that is loaded over address addr in the current process.

This method returns false if no library is loaded over addr or an error occurs, and true if it successfully found a library.

virtual bool getLibraries(std::vector<LibAddrPair> &libs) = 0

This method returns all DSOs that are loaded into the process' address space in the output vector parameter, libs.

This method returns true on success and false on error.

virtual void notifyOfUpdate() = 0

This method is called by the ProcessState when it detects a change in the process' list of loaded libraries. Implementations of LibraryStates should use this method to refresh their lists of loaded libraries.

virtual Address getLibTrapAddress() = 0

Some platforms that implement the System/V standard (Linux, BlueGene/P) use a trap event to determine when a process loads a library. A trap instruction is inserted into a certain address, and that trap will execute whenever the list of loaded libraries change.

On System/V platforms this method should return the address where a trap should be inserted to watch for libraries loading and unloading. The ProcessState object will insert a trap at this address and then call notifyOfUpdate when that trap triggers.

On non-System/V platforms this method should return 0.

3.5.5 Class SymbolLookup

Defined in: symlookup.h

The SymbolLookup virtual class is an interface for associating a symbolic name with a stack frame. Each Frame object contains an address (the RA) pointing into the function (or function-like object) that created its stack frame. However, users do not always want to deal with addresses when symbolic names are more convenient. This class is an interface for mapping a Frame object's RA into a name.

In addition to getting a name, this class can also associate an opaque object (via a void*) with a Frame object. It is up to the SymbolLookup implementation what to return in this opaque object.

The default implementation of SymbolLookup provided by StackwalkerAPI uses the SymLite tool to lookup symbol names. It returns a Symbol object in the anonymous void*.

```
SymbolLookup(std::string exec_path = "");
```

Constructor for a SymbolLookup object.

This method takes an address, addr, as input and returns the function name, out_name, and an opaque value, out_value, at that address. Output parameter out_name should be the name of the function that contains addr. Output parameter out_value can be any opaque value determined by the SymbolLookup implementation. The values returned are used by the Frame::getName and Frame::getObject functions.

This method returns true on success and false on error.

```
virtual Walker *getWalker()
```

This method returns the Walker object associated with this SymbolLookup.

```
virtual ProcessState *getProcessSate()
```

This method returns the ProcessState object associated with this SymbolLookup.

4 Callback Interface Default Implementations

StackwalkerAPI provides one or more default implementations of each of the callback classes described in Section 3.5. These implementations are used by a default configuration of StackwalkerAPI.

4.1 Debugger Interface

This section describes how to use StackwalkerAPI for collecting 3rd party stack walks. In 3rd party mode StackwalkerAPI uses the OS's debugger interface to connect to another process and walk its call stacks. As part of being a debugger StackwalkerAPI receives and needs to handle debug events. When a debugger event occurs, StackwalkerAPI must get control of the host process in order to receive the debugger event and continue the target process.

To illustrate the complexities with running in 3rd party mode, consider the follow code snippet that uses StackwalkerAPI to collect a stack walk every five seconds.

StackwalkerAPI is running in 3rd party mode, since it attached to the target process, pid. As the target process runs it may be generating debug events such a thread creation and destruction, library loads and unloads, signals, forking/execing, etc. When one of these debugger events is generated the OS will pause the target process and send a notice to the host process. The target process will remain paused until the host process handles the debug event and resumes the target process.

In the above example the host process is spending almost all of its time in the sleep call. If a debugger event happens during the sleep, then StackwalkerAPI will not be able to get control of the host process and handle the event for up to five seconds. This will cause long pauses in the target process and lead to a potentially very large slowdown.

To work around this problem StackwalkerAPI provides a notification file descriptor. This file descriptor represents a connection between the StackwalkerAPI library and user code. StackwalkerAPI will write a single byte to this file descriptor when a debug event occurs, thus notifying the user code that it needs to let StackwalkerAPI receive and handle debug events. The user code can use system calls such as select to watch for events on the notification file descriptor.

The following example illustrates how to properly use StackwalkerAPI to collect a stack walk from another process at a five second interval. Details on the ProcDebug class, getNotificationFD method, and handleDebugEvent method can be found in Section 4.1.1. See the UNIX man pages for more information on the select system call. Note that this example does not include all of the proper error handling and includes that should be present when using select.

```
Walker *walker = Walker::newWalker(pid);
ProcDebug *debugger = (ProcDebug *) walker->getProcessState();
std::vector<Frame> swalk;
for (;;) {
    walker->walkStack(swalk);
    struct timeval timeout;
    timeout.tv_sec = 5;
    timeout.tv_usec = 0;
    int max = 1;
    fd_set readfds, writefds, exceptfds;
    FD_ZERO(&readfds); FD_ZERO(&writefds); FD_ZERO(&exceptfds);
    FD_SET(ProcDebug::getNotificationFD(), &readfds);
```

```
for (;;) {
    int result = select(max, &readfds, &writefds, &exceptfds, &timeout);
    if (FD_ISSET(ProcDebug::getNotificationFD(), readfds)) {
        //Debug event
        ProcDebug::handleDebugEvent();
    }
    if (result == 0) {
        //Timeout
        break;
    }
}
```

4.1.1 Class ProcDebug

Defined in: procstate.h

Access to StackwalkerAPI's debugger is through the ProcDebug class, which inherits from the ProcessState interface. The easiest way to get at a ProcDebug object is to cast the return value of Walker::getProcessState into a ProcDebug. C++'s dynamic_cast operation can be used to test if a Walker uses the ProcDebug interface:

```
ProcDebug *debugger;
debugger = dynamic_cast < ProcDebug *> (walker -> getProcessState());
if (debugger != NULL) {
    //3rd party
    ...
} else {
    //1st party
    ...
}
```

In addition to the handling of debug events, described in Section 4.1, the ProcDebug class provides a process control interface; users can pause and resume process or threads, detach from a process, and test for events such as process death. As an implementation of the ProcessState class, ProcDebug also provides all of the functionality described in Section 3.5.4.

```
virtual bool pause(Dyninst::THR_ID tid = NULL_THR_ID)
```

This method pauses a process or thread. The paused object will not resume execution until ProcDebug::resume is called. If the tid parameter is not NULL_THR_ID then StackwalkerAPI will pause the thread specified by tid. If tid is NULL_THR_ID then StackwalkerAPI will pause every thread in the process.

When StackwalkerAPI collects a call stack from a running thread it first pauses the thread, collects the stack walk, and then resumes the thread. When collecting a call stack from a paused thread StackwalkerAPI will collect the stack walk and leave the thread paused. This method is thus useful for pausing threads before stack walks if the user needs to keep the returned stack walk synchronized with the current state of the thread.

This method returns true if successful and false on error.

virtual bool resume(Dyninst::THR_ID tid = NULL_THR_ID)

This method resumes execution on a paused process or thread. This method only resumes threads that were paused by the ProcDebug::pause call, using it on other threads is an error. If the tid parameter is not NULL_THR_ID then StackwalkerAPI will resume the thread specified by tid. If tid is NULL_THR_ID then StackwalkerAPI will resume all paused threads in the process.

This method returns true if successful and false on error.

virtual bool detach(bool leave_stopped = false)

This method detaches StackwalkerAPI from the target process. StackwalkerAPI will no longer receive debug events on this target process and will no longer be able to collect call stacks from it. This method invalidates the associated Walker and ProcState objects, they should be cleaned using C++'s delete operator after making this call. It is an error to attempt to do operations on these objects after a detach, and undefined behavior may result.

If the leave_stopped parameter is true StackwalkerAPI will detach from the process but leave it in a paused state so that it does resume progress. This is useful for attaching another debugger back to the process for further analysis. The leave_stopped parameter is not supported on the Linux platform and its value will have no affect on the detach call.

This method returns true if successful and false on error.

virtual bool isTerminated()

This method returns **true** if the associated target process has terminated and **false** otherwise. A target process may terminate itself by calling exit, returning from main, or receiving an unhandled signal. Attempting to collect stack walks or perform other operations on a terminated process is illegal an will lead to undefined behavior.

A process termination will also be signaled through the notification FD. Users should check processes for the isTerminated state after returning from handleDebugEvent.

static int getNotificationFD()

This method returns StackwalkerAPI's notification FD. The notification FD is a file descriptor that StackwalkerAPI will write a byte to whenever a debug event occurs that need. If the user code sees a byte on this file descriptor it should call handleDebugEvent to let StackwalkerAPI handle the debug event. Example code using getNotificationFD can be found in Section 4.1.

StackwalkerAPI will only create one notification FD, even if it is attached to multiple 3rd party target processes.

When this method is called StackwalkerAPI will receive and handle all pending debug events from each 3rd party target process to which it is attached. After handling debug events each target process will be continued (unless it was explicitly stopped by the ProcDebug::pause method) and any bytes on the notification FD will be cleared. It is generally expected that users will call this method when a event is sent to the notification FD, although it can be legally called at any time.

If the block parameter is true, then handleDebugEvents will block until it has handled at least one debug event. If the block parameter is false, then handleDebugEvents will handle any currently pending debug events or immediately return if none are available.

StackwalkerAPI may receive process exit events for target processes while handling debug events. The user should check for any exited processes by calling ProcDebug::isTerminated after handling debug events.

This method returns true if successful and false on error.

4.2 FrameSteppers

Defined in: framestepper.h

StackwalkerAPI ships with numerous default implementations of the FrameStepper class. Each of these FrameStepper implementations allow StackwalkerAPI to walk a type of call frames. Section 3.5.1 describes which FrameStepper implementations are available on which platforms. This sections gives a brief description of what each FrameStepper implementation does. Each of the following classes implements the FrameStepper interface described in Section 3.5.2, so we do not repeat the API description for the classes here.

Several of the FrameSteppers use helper classes (see FrameFuncStepper as an example). Users can further customize the behavior of a FrameStepper by providing their own implementation of these helper classes.

4.2.1 Class FrameFuncStepper

This class implements stack walking through a call frame that is setup with the architectures standard stack frame. For example, on x86 this FrameStepper will be used to walk through stack frames that are setup with a push %ebp/mov %esp,%ebp prologue.

4.2.1.1 Class FrameFuncHelper FrameFuncStepper uses a helper class, FrameFuncHelper, to get information on what kind of stack frame it's walking through. The FrameFuncHelper will generally use techniques such as binary analysis to determine what type of stack frame the FrameFuncStepper is walking through. Users can have StackwalkerAPI use their own binary analysis mechanisms by providing an implementation of this FrameFuncHelper.

There are two important types used by FrameFuncHelper and one important function:

```
typedef enum {
    unknown_t=0,
```

```
no_frame,
    standard_frame,
    savefp_only_frame,
} frame_type;
```

The frame_type describes what kind of stack frame a function uses. If it does not set up a stack frame then frame_type should be no_frame. If it sets up a standard frame then frame_type should be standard_frame. The savefp_only_frame value currently only has meaning on the x86 family of systems, and means that a function saves the old frame pointer, but does not setup a new frame pointer (it has a push %ebp instruction, but no mov %esp,%ebp). If the FrameFuncHelper cannot determine the frame_type, then it should be assigned the value unknown_t.

```
typedef enum {
    unknown_s=0,
    unset_frame,
    halfset_frame,
    set_frame
} frame_state;
```

The frame_state type determines the current state of function with a stack frame at some point of execution. For example, a function may set up a standard stack frame and have a frame_type of standard_frame, but execution may be at the first instruction in the function and the frame is not yet setup, in which case the frame_state will be unset_frame.

If the function sets up a standard stack frame and the execution point is someplace where the frame is completely setup, then the frame_state should be set_frame. If the function sets up a standard frame and the execution point is at a point where the frame does not yet exist or has been torn down, then frame_state should be unset_frame. The halfset_frame value of frame_state is currently only meaningful on the x86 family of architecture, and should if the function has saved the old frame pointer, but not yet set up a new frame pointer.

```
typedef std::pair<frame_type, frame_state> alloc_frame_t;
virtual alloc_frame_t allocatesFrame(Address addr) = 0;
```

The allocatesFrame function of FrameFuncHelper returns a alloc_frame_t that describes the frame_type of the function at addr and the frame_state of the function when execution reached addr.

If addr is invalid or an error occurs, allocatedFrame should return alloc_frame_t(unknown_t, unknown_s).

4.2.2 Class SigHandlerStepper

The SigHandlerStepper is used to walk through UNIX signal handlers as found on the call stack. On some systems a signal handler generates a special kind of stack frame that cannot be walked through using normal stack walking techniques.

4.2.3 Class DebugStepper

This class uses debug information found in a binary to walk through a stack frame. It depends on SymtabAPI to read debug information from a binary, then uses that debug information to walk through a call frame.

Most binaries must be built with debug information (-g with gcc) in order to include debug information that this FrameStepper uses. Some languages, such as C++, automatically include stackwalking debug information for use by exceptions. The DebugStepper class will also make use of this kind of exception information if it is available.

4.2.4 Class AnalysisStepper

This class uses dataflow analysis to determine possible stack sizes at all locations in a function as well as the location of the frame pointer. It is able to handle optimized code with omitted frame pointers and overlapping code sequences.

4.2.5 Class StepperWanderer

This class uses a heuristic approach to find possible return addresses in the stack frame. If a return address is found that matches a valid caller of the current function, we conclude it is the actual return address and construct a matching stack frame. Since this approach is heuristic it can make mistakes leading to incorrect stack information. It has primarily been replaced by the AnalysisStepper described above.

4.2.6 Class BottomOfStackStepper

The BottomOfStackStepper doesn't actually walk through any type of call frame. Instead it attempts to detect whether the bottom of the call stack has been reached. If so, BottomOfStackStepper will report gcf_stackbottom from its getCallerFrame method. Otherwise it will report gcf_not_me. BottomOfStackStepper runs with a higher priority than any other FrameStepper class.
